

Credit Ratings in Sovereign Bond Markets

Abstract

How does credit market segmentation affect the default risk of developing countries? This paper explores the impact of market segmentation resulting from sovereign credit ratings on default risk and emphasizes its disciplinary role in shaping borrowing behavior. Empirical analysis suggests that downgrades from investment-grade to junk ratings are associated with a 30-basis-point spread increase. To account for this, I develop a quantitative sovereign default model incorporating credit ratings and a segmented market structure derived from ratings. I calibrate the segmentation parameter to match the observed spread movements during downgrades and find that the higher spread implies a 200-basis-point higher discount rate on junk bonds than comparable non-junk bonds. In the model, when a country accumulates debt beyond a threshold, it triggers downgrades, resulting in sovereign bonds being priced by more impatient lenders, leading to higher interest rates. Consequently, the government borrows less, reducing default risk and raising the overall bond price schedule. While the segmentation makes the country worse off in the steady-state debt level, it can benefit the government in low-debt states by mitigating overborrowing friction associated with long-maturity structures, resulting in welfare gains. An analysis of an optimal rating rule suggests that a looser rating rule diminishes these welfare gains.

1 Introduction

This paper examines the regulatory usage of sovereign credit ratings, particularly the constraints that institutional investors face in holding sovereign bonds with low ratings. The study investigates the consequences of these constraints on capital market segmentation and how a country's sovereign ratings affect the external credit supply it receives in an open economy. When a country is downgraded to junk status, it loses a group of investors who are subject to prudential regulations (Dale and Thomas (1991); Ferri et al. (1999); Rigobon (2002)). As a result, a junk-rated country must rely on a different set of investors to raise funds compared to an investment-grade country. This market segmentation by sovereign credit ratings has a greater impact on developing countries than on developed countries. Developing countries are more likely to experience downgrades to junk during recessions or political instability, whereas advanced economies are seldom rated as junk.¹

Along with the consequence of capital market segmentation, this paper aims to understand the role of sovereign ratings in emerging markets. While sovereign ratings have significant implications for credit access and market yield (Cantor and Packer (1996)), few studies have analyzed their impacts on emerging markets and often neglect the endogenous behavior of the sovereign.² In reality, countries have the ability to influence their credit ratings, and they may want to manage their ratings in favor of themselves. For example, Moody's upgraded Vietnam's rating as Vietnam's National Assembly conducted prudent debt management policies (including lowering the public debt ceiling).³ This paper addresses this gap by providing the first quantitative analysis of how developing countries respond to regulatory constraints imposed by sovereign credit ratings in segmented market structures.

Unlike the previous literature, this paper highlights the disciplinary role of sovereign ratings on countries' borrowing. Specifically, accumulating debt beyond a certain level may cause a downgrade to junk, leading to higher interest rates on the country's bonds. The country takes these consequences into account and may choose to reduce its debt level to avoid downgrades or to exit the junk territory. This disciplinary role ultimately lowers

¹According to S&P sovereign rating, Sweden, the United Kingdom, Netherlands, and the United States have downgraded once during the entire rating history, and the downgrade is from AAA (the highest rating level) to AA+ (the second highest rating level). Germany and Switzerland have been keeping their rating as AAA throughout their rating history. Singapore and Hong Kong constantly improved sovereign ratings and have kept their investment-grade status throughout their history. During the European debt crisis, only Portugal and Greece experienced downgrading to junk. Spain, Italy, and Ireland experienced multi-notch downgrades, but they never downgraded to junk.

²For example, Ferri et al. (1999) is motivated by Asian financial crisis episodes and concludes that sovereign ratings can represent another systemic risk to emerging markets. The paper does not study how those countries responded upon they experienced a downgrade.

³<https://www.moodys.com/research/Moodys-upgrades-Vietnams-rating-to-Ba2-outlook-changed-to-stable--P468174>

default risk and may enable the country to issue bonds at a more favorable price. The segmentation by credit ratings encourages the country to keep the default risk relatively low, and the country is less vulnerable to sudden output drop. Also, this effect can reduce overborrowing inefficiency stemming from bond maturity structure and improve the country's welfare. Incorporating the endogenous response of the sovereign is critical for this result to arise.

To this goal, I build a quantitative sovereign default model following [Arellano \(2008\)](#), [Hatchondo and Martinez \(2009\)](#), and [Chatterjee and Eyigungor \(2012\)](#), and incorporate credit ratings and a segmented market structure. In my model, the sovereign borrows in long-term bonds from the international credit market to offset income shocks and to front-load its expenditure. It also chooses to default on its outstanding debt or not. A credit rating represents the country's default risk. But the rating also determines which set of creditors the government borrows from. When the country is high-rated (or investment-grade), it issues bonds in a high-rating bond market and vice versa for the low-rated (or junk) bond market. Therefore, the segmented market structure generates different bond price schedules depending on the rating. I assume that those price schedules are different by the discount rate of the creditors. Those discount rate parameters control the degree of segmentation and are calibrated by matching statistics observed in data.

To discipline the segmentation parameter, I exploit an empirical statistic from an emerging market panel data. I use sovereign bond spreads and sovereign rating data to capture the change in spreads when a country's rating changes from investment grade to junk. I find that countries experience an increase of a 30-basis-point in their yields when they are downgraded to junk. This increase is compared to those countries with similar economic fundamentals but not experiencing a downgrade to junk. This higher spread is robust to several other specifications. I find that the increase in bond spread is higher for those countries that are downgraded to junk than those that are downgraded but do not cross the regulatory threshold (downgraded within investment grade or junk grade). Those empirical findings are consistent with the regulatory usage of sovereign ratings.

By replicating this statistic, the calibrated segmentation parameter represents a higher discount rate of the low-rated bond market than that of the high-rated one. This implies that a low-rated bond is charged a higher interest rate than a bond with the same default risk but a high rating. This discourages the government from accumulating its debt beyond the downgrade threshold. Although it prefers front-loaded expenditure, the government finds it optimal to reduce its debt level. Debt reduction as an optimal policy is apparent, particularly when the economy is near a downgrade threshold. The debt issuance in a controlled manner makes the country resilient to negative output shocks, and therefore, default happens less

often. This lower frequency of default is embedded in the pricing schedule as a lower default risk compensation. This is shown by comparing the calibrated benchmark economy to the counterfactual economy without ratings. By targeting the economy to match the average of the panel data, the model simulation shows that the frequency of default, default risk, and average spread are lower in the benchmark than in the counterfactual.

Next, I study whether countries can be better off with ratings and the resulting segmentation. I find that, under the calibration, the country is worse off with ratings at the steady-state level of debt. However, the country can be better off at low levels of debt. There are opposite forces for this welfare implication. The welfare benefit arises from the disciplinary effect: the country can borrow at a favorable price. On the other hand, borrowing less and abstaining from consumption reduces welfare. Another welfare cost arises during the period when the country's rating is low: higher yield from impatient lenders. The calibrated sovereign is so impatient that the welfare cost quantitatively dominates the welfare benefit. However, I find that the segmentation can make the country better off in low-debt states.

Now, I investigate how the maturity of bonds affects the welfare gains associated with sovereign ratings. I construct a counterfactual economy where the issued debt is a one-period bond.⁴ I find that in a counterfactual economy, the use of sovereign ratings results in a decrease in welfare for all levels of debt. Ratings have a positive effect as they act as a commitment device for the country's future borrowing behavior. This partially resolves the debt-dilution problem under long-term debts. The issue with long-term debt is that when a new debt is issued, the country cannot commit to its future borrowing behavior, making long-term debt more expensive than one-period debt. Ratings give lenders a rational basis to anticipate that the country will not choose to borrow more in the future, especially above the junk cutoff. This anticipatory behavior of lenders leads to paying a higher price, resulting in welfare gains under long-term debts.

Conducting a counterfactual exercise using alternative segmentation rules suggests that loose rules generate negative welfare implications because they weaken the disciplinary effect and lower the welfare benefits of segmentation.

This paper is organized as follows: [Section 1.1](#) goes over the literature review. [Section 2](#) discusses the details of sovereign ratings and examples of the regulatory usage of sovereign ratings. [Section 3](#) presents the empirical findings from emerging market data. [Section 4](#) describes the model, and [Section 5](#) explains the calibration strategy. [Section 6](#) shows the main quantitative results: the disciplinary effect of sovereign ratings, welfare implications,

⁴In the benchmark, the issued debt is a 10-year bond.

and the role of bond maturity. Lastly, [Section 7](#) concludes the paper.

1.1 Related literature

This paper contributes to two related strands of literature. First, this paper is related to the quantitative sovereign default literature. Second, the paper is closely related to a broad set of empirical papers that analyze the impact of credit ratings on sovereigns, especially developing countries.

The sovereign default literature bases its theoretical framework developed in [Eaton and Gersovitz \(1981\)](#) and extended by [Aguiar and Gopinath \(2006\)](#), [Arellano \(2008\)](#), [Hatchondo and Martinez \(2009\)](#), and [Chatterjee and Eyigungor \(2012\)](#). The survey papers, [Aguiar and Amador \(2014\)](#) and [Aguiar and Amador \(2021\)](#), document the sovereign default literature in detail. The Eaton-Gersovitz model is about a government that faces income risk and borrows, using a defaultable but otherwise noncontingent bond. The risk-averse government borrows to smooth consumption, but its impatient preference generates front-loading consumption. The key feature of the model is that the government cannot commit to repay its debts. This class of model is able to replicate the countercyclical movement of interest rates in emerging markets, which is documented in [Aguiar and Gopinath \(2007\)](#) and [Neumeyer and Perri \(2005\)](#). This paper departs from assuming a single international capital market and models a rich international capital market structure. In particular, this paper assumes that due to regulatory constraints, the international capital market is segmented by sovereign credit rating. The capital market where sovereign bonds are traded shifts as the country's credit ratings change, which is endogenously determined.

Including long-term bond maturity allows the model to match high debt levels and high volatility of interest rates, as discussed in [Hatchondo and Martinez \(2009\)](#) and [Chatterjee and Eyigungor \(2012\)](#). Although these features are commonly observed in the data, one-period bond models have a limit to generate quantitatively. Moreover, models of long-term bonds introduce unique friction, “debt delusion”, into the analysis. Under long-term bonds, sovereigns may have incentives to reduce the value of remaining debts by issuing more bonds. The bondholders, after anticipating this potential behavior, may charge high interest, and, as a consequence, the sovereigns end up with a high level of debt. This friction is vital in the welfare implication of the segmentation in this paper, which is discussed in [Section 4.7](#). Long-term bond maturity models have a computational challenge, as discussed in [Aguiar et al. \(2020\)](#). [Dvorkin et al. \(2021\)](#) employs discrete choice methods to overcome the computational challenge, making the quantitative sovereign default model under long-term bonds tractable. I follow their methods and include extreme value shocks to handle

the computational challenge. The method is explained in detail in [Section 5](#).

There are ample empirical papers about sovereign credit ratings and their impact on sovereign bond spreads (see, for example, [Reisen and Von Maltzan \(1998\)](#), [Cantor and Packer \(1996\)](#), [Ferri et al. \(1999\)](#), [Reisen and Von Maltzan \(1999\)](#), [Kaminsky and Schmukler \(2002\)](#), [Kräussl \(2005\)](#), [Ismailescu and Kazemi \(2010\)](#), [Afonso et al. \(2012\)](#), [Chen et al. \(2016\)](#), [Drago and Gallo \(2016\)](#), [Hanusch et al. \(2016\)](#), [El-Shagi and von Schweinitz \(2018\)](#), and [Lu and Qu \(2023\)](#)). Using cross-section data, [Cantor and Packer \(1996\)](#) find that per-capital income, external debt, and inflation are crucial determinants of sovereign credit ratings, and sovereign credit ratings summarize the country’s macroeconomic fundamentals well. Using event studies, the paper highlights that credit ratings can independently affect spreads. They show that the spread movement follows the announcement of the credit ratings changes in an expected direction. In particular, the announcement for a non-investment grade, or junk grade, affects spread to a greater degree than that for an investment grade. Along with these findings, this paper focuses on the distinction between investment-grade bonds and junk bonds by incorporating regulations on investing in low-rating bonds.

[Hanusch et al. \(2016\)](#) and [Drago and Gallo \(2016\)](#) are closest to the empirical analysis of this paper. Both papers focus on the regulatory usage of sovereign ratings. [Hanusch et al. \(2016\)](#) use panel regression to estimate the impact of downgrades from investment grade to junk. They estimate the impact on short-term borrowing using Treasury Bills, whereas this paper finds evidence on long-term borrowing, which is consistent with the quantitative model. [Drago and Gallo \(2016\)](#) use an event study approach to provide evidence of a regulatory threshold. They compare the spread response to downgrades crossing investment grade/junk classification and to downgrades without crossing it. They find that the CDS spread reacts intensely to downgrades crossing the threshold. This paper takes a similar approach, and its findings are consistent with the literature. The paper contributes to the literature by estimating how different the junk bonds market is from the investment-grade bonds market and quantifying that difference in terms of the discount rate.

2 Ratings and regulations on institutional lenders

Sovereign credit ratings are the assessment by credit rating agencies, for example, Moody’s and Standard and Poors’, of the likelihood of a government defaulting on its debt obligations. In recent decades, the demand for sovereign ratings has risen rapidly. In the early phase of the 20th century, Moody’s rated roughly 50 bonds of central governments. These were mainly issued by developed countries, including the United States. The number has risen to more than 130 countries as of today. This growth is because sovereign ratings facilitate countries

to access international capital markets: International investors, particularly United States investors, prefer rated government securities over unrated securities of similar default risk (Cantor and Packer (1995), Luitel and Vanpée (2018)). In recent decades, developing and low-income countries, for example, African countries, have newly had their sovereign bonds assessed for credit ratings. Developing countries pay considerable attention to sovereign ratings as a means of raising external funds from international capital markets (Cantor and Packer (1995)).

Another reason developing economies care about their credit ratings is because their rating change could trigger regulatory constraints on investing their bonds. Rating-based regulations on institutional investors are intended to prevent speculative investing under prudential measures. Those regulations originated from the Volcker Rule and the Dodd-Frank law in the United States⁵ (Duffie (2012), Bernstein (2019)), and the Basel II framework spread rating-based rules widely in advanced economies as well. The restrictions are often in the form of imposing the minimum level of rating for securities investment and holdings. A well-known notion for the minimum level is the speculative grade or junk: equal to or below BB+ under S&P and Fitch or Ba1 under Moody's. Therefore, when a developing country has its sovereign rating downgraded to junk, its sovereign bonds are subject to prudential regulations, and potential investors are limited to holding junk bonds due to regulatory concerns.

South Africa in 2020 provides anecdotal evidence of developing countries' concern about being junk-rated. In November 2022, Moody's and Fitch downgraded South Africa deeper into junk territory. South Africa's Minister of Finance said, "The decision by Fitch and Moody's ... is a painful one. ... Continuous rating downgrades will translate to unaffordable debt costs, deteriorating asset values"⁶ According to JP Morgan estimates, the downgrade of South Africa could trigger the forced selling of up to \$2.4 billion worth of South Africa's dollar-denominated Eurobonds.⁷ Another piece of anecdotal evidence is Greece in 2010. As its debt crisis evolved, Greece was downgraded to junk by S&P and Moody's. According to Barclays Capital, a British universal bank, this downgrade is estimated to result in Greek government bonds worth \$252 billion being excluded from its bond indexes.^{8 9}

⁵The Volcker Rule exempts the United States treasuries and federal agency bonds, but it does not exempt securities issued by foreign countries.

⁸<https://www.wsj.com/articles/BL-MB-23516>

⁹Investment decision by credit ratings is also present in internal rules of index funds. Investment-grade (rating equal to or above BBB- under S&P and Fitch or Baa3 under Moody's) bond indexes are forced to

As documented in [Kiff et al. \(2012\)](#) and [BIS \(2009a\)](#), credit ratings are often used by authorities to classify securities in legislation, regulations, and supervisory policies. Credit ratings affect the bond demand of institutional lenders and serve as triggers in investment decisions under regulations. These regulations are mostly motivated by prudential measures and have the goal of sheltering institutional investors' portfolios from high risks. There are nationally recognized statistical rating organizations (NRSROs) under the United States Securities and Exchange Commission (the U.S. SEC) and these regulations adopt credit ratings released by NRSROs.

Basel II is one of the prominent examples of the usage of credit ratings on regulations. Risk-based capital requirements under a standardized approach use credit ratings to map credit risks to risk weights or capital charges. Many advanced economies, for example, the European Union, Australia, Canada, Japan, and the United States, incorporate the Basel II framework into assessing the credit quality of securities in banking sectors. Also, the central banks set a limitation for acceptable collateral and margin requirements. For example, the European Central Bank (ECB) specifies the minimum rating level for the eligible collateral of commercial banks ([ECB \(2013\)](#)).

Not only banking sector is affected, but insurance sector is also affected. Mostly, insurance companies or pension funds are regulated to hold bonds above the minimum rating. In Japan, for example, estimating credit risks for insurance companies is done by calculating the solvency margin ratios, and credit ratings are used for the calculation. In the case of the United Kingdom, the Insurance Prudential Sourcebook relies on credit ratings for insurance capital requirements. In Canada, the Office of the Superintendent of Financial Institutions (OSFI) states, in its life insurer capital guideline, that "A company must consistently follow the latest ratings from a recognized, widely followed credit rating agency. Only where that rating agency does not rate a particular instrument, the rating of another recognized, widely followed credit rating agency may be used." These restrictions are present also in state legislation. For example, New York state insurance law mentions that an insurer may insure municipal obligation bonds that are not investment grade as long as at least 95 % of the insurer's aggregate liability is investment grade (see [BIS \(2009b\)](#)).

Non-investment grade is often subject to these regulation, and investment/non-investment is a commonly-used regulatory threshold. Investment grade is above BBB- under the Standard and Poor's and Fitch rating system or Baa3 under Moody's system. Non-investment grade which is often called a junk grade is below BB+ under the Standard and Poor's and Fitch system or Ba1 under Moody's system. Regulatory restrictions imply that it is costly

sell their junk bonds following internal guidelines. Dropping out major bond indices could trigger additional forced-sell by other investors.

to hold non-investment grade (or junk grade) securities or that the potential holders of non-investment grade sovereign debt are limited. As documented in [Rigobon \(2002\)](#), upgrading to investment grade means that broader types of investors, for example, pension funds, and insurance companies, can hold the sovereign bonds.

3 Empirical evidence

In this section, I present the empirical relationship between countries' credit ratings and their spreads. I investigate bond spread response as a country's credit rating changes across a regulatory threshold. In what follows, I use investment grade and junk grade as the regulatory threshold.

The country's default risk affects the bond spread and the credit rating. In regression, I control for the country's default risk using its macroeconomic fundamentals. I show that the country experiencing downgrades across the regulatory threshold is associated with a statistically higher bond spread compared to the country with similar macroeconomic fundamentals that does not experience a downgrade. I use the coefficient estimate of the downgrade dummy variable to calibrate the market segmentation parameter later in the calibration section. As a robust check, I compare the spread response to downgrades across the threshold to the spread response to the same degree of the downgrades but not crossing the threshold. I find a higher spread with downgrades across the threshold than downgrades not crossing the threshold.

[Section 3.1](#) describes the emerging market panel data and data sources. [Section 3.2](#) shows the main empirical findings.

3.1 Data description

The observation of interest is how the bond market responds to a regulatory constraint triggered by a change in the credit rating of a bond. I use bond spreads as the measure of the bond market response. In particular, I use the JP Morgan's Emerging Market Bond Index (EMBI) spread in the Global Economic Monitor (GEM) in the World Bank. These spreads are defined as the weighted averages of the bond yield spread of US dollar-denominated external debts issued by sovereigns and sovereign entities over corresponding the United States government debt securities (see [Comelli \(2012\)](#)). For a country's credit rating, I use

the Standard and Poor’s sovereign credit ratings. ¹⁰ ¹¹Under the Standard and Poor’s (S&P) criteria, the regulatory threshold of interest lies between BBB- and BB+. In other words, a country with S&P ratings above BBB- is investment-graded and the one with S&P ratings below BB+ is junk-graded.

The sample period is from January 1998 to December 2019. I choose a set of countries that have experienced being both investment-graded ratings and junk-graded ratings throughout the sample period, along with data availability. Russia has a default experience during the sample period (year 1999), and I exclude the country as an outlier. The 12 countries in the sample are Azerbaijan, Brazil, Bulgaria, Colombia, Croatia, Hungary, Mexico, Namibia, Panama, Peru, the Philippines, and South Africa. Bond spreads and ratings are calculated monthly. For each country’s economic fundamentals, I use GDP growth rate, GDP per capita, gross debt to GDP ratio, government revenue, current account, and inflation rate. The data is from the World Economic Outlook (WEO) in the IMF, and it is at a yearly frequency. [Appendix A](#) lists the detailed definition and source of the dataset.

Table 1: Summary statistics of bond spreads (bps) by ratings

| | <i>Investment grade</i> | | | | <i>Junk</i> | | | | |
|--------------|-------------------------|-------|-------|-------|-------------|-------|--------|--------|--------|
| | A- | BBB+ | BBB | BBB- | BB+ | BB | BB- | B+ | B |
| Mean | 50.7 | 187.4 | 183.7 | 263.8 | 331.7 | 357.1 | 444.4 | 884.9 | 782.4 |
| Median | 53.1 | 168.6 | 172.2 | 226.1 | 312.1 | 315.3 | 393.9 | 751.3 | 803.1 |

Source: the World bank, S&P, Fitch

[Table 1](#) shows the summary statistics of bond spreads by ratings. These observations are at a monthly frequency. The sample is centered around the regulatory threshold between

¹⁰The Standard and Poor’s is one of the major credit rating agencies authorized as an NRSRO. The literature fairly documents that the ratings of different credit rating agencies rarely differ much (see [Ferri et al. \(1999\)](#)). [El-Shagi and von Schweinitz \(2018\)](#) documented empirically that the mean absolute difference to the average rating level is 0.5 notches. It means ratings across agencies are far less than one notch apart on average. Therefore, the empirical findings would not change much by using credit ratings of different agencies, for example, Moody’s and Fitch.

¹¹For Namibia, S&P rating is not available. In this case, I use the Fitch rating as an alternative since it has the same rating scale.

Figure 1: Spread by rating

Figure 2: Downgrade to junk and spread dynamics

BBB- and BB+. A low rating indicates the low credibility of creditors, and as expected, a lower rating is associated with higher bond spreads. Moreover, bond spreads become more volatile as ratings are lower. Figure 1 visualizes these patterns: as the rating is lower, the spread is higher and more volatile on average.

Table 2 shows the monthly changes in ratings. A downgrade is defined as an event where a country’s rating changes to a lower level than the rating level of the previous month. An upgrade is defined as an event where a country’s rating changes to a higher level than the rating level of the previous month. In my sample, every rating changes by one notch. As shown in the table, countries’ ratings are persistent, and a country’s credit rating has a 97% likelihood of not changing in the next month. The literature has documented that countries’ ratings tend to be persistent. (El-Shagi and von Schweinitz (2018)). Table A1 lists the entire downgrade episode in the dataset, which is the main event of interest.

This paper is interested in bond market segmentation by ratings (investment-grade bonds and junk bonds), and the change in ratings across the two markets is the event of interest in particular. Figure 2 shows the dynamics of spread during downgrade from investment-grade to junk. The horizontal axis indicates the timing of downgrades: the country is investment-grade when $time < 0$, downgrades from investment-grade to junk take place at $time = 0$, and the country is junk when $time > 0$. The spread rises before the downgrade, picks the highest right after the downgrade episode, and remains high afterward.

3.2 The empirical results

After constructing the sample, I investigate how yields respond to a change in ratings. I focus on downgrades where regulatory restrictions are triggered, in particular, when a country’s

Table 2: Monthly rating changes

| | Count | Frequency |
|-----------|-------|-----------|
| No change | 2,776 | 0.97 |
| Downgrade | 31 | 0.01 |
| Upgrade | 49 | 0.02 |

Note: No change indicates a rating of a country that has the same rating as that in the previous month. Downgrade indicates a rating of a country that has a lower rating than that in the previous month. Upgrade indicates a rating of a country that has a higher rating than that in the previous month. Here, I use S&P rating scale. Source: S&P, Fitch

rating changes from investment grade to junk.

I conduct the following two-way fixed effect regression:

$$spread_{it} = \beta_0 + \beta_1 DowntoJunk_{it} + \Gamma X_{it} + \alpha_i + \delta_t + \epsilon_{it} \quad (1)$$

The variable $spread_{it}$ is country i 's bond spread at time t , $DowntoJunk_{it}$ is a dummy variable which equals to one if the country i 's rating is investment grade at time $t - 1$ and junk at time t and equals to zero otherwise.

X_{it} is a set of control variables, including the country's economic fundamentals and lagged spread. Following [Cantor and Packer \(1996\)](#), I include the following variables to control a country's underlying economic fundamentals that affect both spreads and sovereign ratings: GDP growth rate, GDP per capita, gross debt to GDP ratio, government revenue, current account, inflation rate. Unlike ratings and spreads in monthly frequency, economic fundamental variables are yearly. To capture the movement of the fundamentals within a year, I include the country's lagged spread (the spread of the previous month) as another control variable. I include country-fixed effect α_i and time-fixed effect δ_t in monthly frequency. The coefficient of interest is the downgrade dummy coefficient β_1 .

The left column of [Table 3](#) shows the regression result. The coefficient estimate of $DowntoJunk$ is positive and statistically significant, implying that a country's downgrade across the regulatory threshold is associated with an increase in bond spreads. The bond spreads, on average, increase by 30 bps when the country downgrades from investment grade to junk compared to the spread of a country with similar fundamentals but that has not experienced the downgrade to junk. This finding is consistent with the literature, for example,

Table 3: Estimated spread response to downgrade to junk

| | (1) Spread | (2) Spread |
|--------------------------|----------------------|----------------------|
| <i>Downgrades</i> | | |
| Within Invst | | 16.75* (9.849) |
| Down to Junk | 30.26*** (11.22) | 30.77*** (11.21) |
| Within Junk | | 17.29* (9.332) |
| <i>Controls</i> | | |
| Lagged spread | 0.974*** (0.005) | 0.974*** (0.005) |
| GDP growth | -0.197 (0.340) | -0.134 (0.340) |

Note: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. Standard errors in parentheses. The regression (1) is the result of the regression equation (1). The regression (2) is the result of the regression equation (2). In all specifications, the dependent variable is EMBI+ sovereign bond spread. DowntoJunk is a dummy variable that equals to 1 when a country's S&P sovereign rating is above or equal to BBB- in period $t - 1$, and below or equal to BB+ in period t . Lag spread is a 1-month lag variable.

Hanusch et al. (2016). They also find a positive and significant spread response to a country’s downgrades. Unlike them, who use short-term bond (60-day Treasury bill) spreads, I use long-term bond spreads, which is consistent with the specification of the quantitative model in Section 5 and 6.

The estimate is robust to other specifications. I include other downgrade dummies in the regression and compare the coefficients across the dummies. *withinJunk* and *withinInvst* variables represent similar downgrades. The variable *withinJunk* captures downgrade within junk: downgrade events either from BB+ to BB or from BB to BB-. Similarly, the variable *withinInvst* denotes downgrades within investment grade: downgrade events either from BBB+ to BBB or from BBB to BBB-. Both dummies are still near investment-grade and junk threshold (between BBB- and BB+).

Formally, the regression with different downgrade dummies is as follows:

$$\begin{aligned} spread_{it} = & \beta_0 + \beta_1 DowntoJunk_{it} \\ & + \beta_2 withinJunk_{it} + \beta_3 withinInvst_{it} + \Gamma X_{it} + \alpha_i + \delta_t + \epsilon_{it} \quad (2) \end{aligned}$$

where $withinJunk_{it} = 1$ when a country i ’s rating is either BBB+ at time $t - 1$ and BBB at time t or BBB at time $t - 1$ and BBB- at time t . $withinInvst_{it} = 1$ when a country i ’s rating is either BB+ at time $t - 1$ and BB at time t or BB at time $t - 1$ and BB- at time t . The variables of interest are β_1 , β_2 and β_3 .

The right column of Table 3 shows the regression result. Downgrades crossing the threshold, *DowntoJunk*, are associated with higher spreads than downgrades not crossing the threshold, *withinJunk* and *withinInvst*. This is consistent with the interpretation that a downgrade from investment-grade to junk is particularly important and could be related to regulatory concerns. In general, downgrade events are negative news about the economy, and a positive sign for the downgrade coefficient is expected. However, the magnitude of the coefficient estimates is different whether the country’s rating crosses the regulatory threshold or not. Furthermore, the downgrades crossing the threshold are statistically more significant than downgrades not crossing the threshold.

This result with different downgrade dummies is consistent with the literature. Using the CDS spreads of European countries, Drago and Gallo (2016) find that crossover downgrades have a significantly greater impact than non-crossover downgrades. They conclude that downgrades leading to a country’s rating category change imply intense reactions from investors due to regulatory constraints. The contribution of part of the paper is to use a broader set of countries than just European countries to show the evidence of the regulatory aspect of sovereign ratings. Next, I use this empirical evidence to discipline the quantitative

model.

In [subsection A.1](#), I show the regression result under different regression specifications.

4 The model

Motivated by the credit market segmentation that depends on credit ratings, I develop a dynamic small open-economy model. The model incorporates credit ratings and a global credit market segmented by these ratings. In addition, it includes a sovereign that borrows in long-term debts and strategically defaults under the timing framework proposed by [Eaton and Gersovitz \(1981\)](#). Including long-term debt is important as it allows the model to quantitatively match the high levels of debt observed in countries experiencing debt crises, a challenge that one-period debt models struggle with. (see, for example, [Hatchondo and Martinez \(2009\)](#), [Chatterjee and Eyigungor \(2012\)](#)) Furthermore, bond maturity plays a vital role in determining the welfare implication of market segmentation. As the literature suggests (see, for example, [Chatterjee and Eyigungor \(2012\)](#), [Hatchondo et al. \(2016\)](#)), debt dilution problem is present in long-term debts, which constitutes the main friction in the model.

4.1 Model Environment

Time is discrete and infinite $t \in \{0, 1, \dots, \infty\}$. The economy consists of a country, a global credit market, and the country's credit rating agency. The sovereign maximizes its expected and discounted lifetime utility. Its utility comes from expenditure each period under budget constraints. The sovereign faces a stochastic output process and has an outstanding debt. The sovereign can choose to default on its outstanding debt. If so, the country is exempted from paying all debts, but faces a cost. Under no default, the country pays the debt service and rolls over its debt by issuing new bond. The credit market is segmented by a credit rating. From which of these the sovereign raises their bond revenue depends on the credit rating the sovereign is assigned.

I model the credit rating as follows: it indicates the country's credibility and is assigned every period based on the country's default risk for next period. Not only does it indicate how likely the country is to default next period, but it determines the market where the sovereign issue new bonds. The model has multiple credit markets with a representative lender for each. I assume that the representative lender in each market is different, in particular different by discount factor. This discount factor is used for pricing the bonds. I focus on Markov equilibrium.

4.2 Timing

Following [Eaton and Gersovitz \(1981\)](#), the timing of the model within a period is as follows:

1. Output y realizes with inherited debt b .
2. The country chooses to default on the debt or repay.
3. Conditional on repayment, the country chooses a new debt level b' .
4. Credit rating r is assigned conditional on b' .
5. Bonds are traded in the appropriate credit market conditional on the rating. The sovereign raises bond revenue and chooses its expenditure.

4.3 The sovereign's problem

The state of the economy is output, y , and the outstanding debt level, b . Output is stochastic and exogenous. I assume it follows an AR(1) process with persistence ρ and volatility η . I estimate the parameters for the process from the emerging market panel data in the empirical section.

The debt is in a long-term, and defaultable but otherwise non-contingent bond. Following [Hatchondo and Martinez \(2009\)](#) and [Chatterjee and Eyigungor \(2012\)](#), I consider random maturity bonds. I assume that every bond randomly matures at the rate of λ in each period. Each bond pays coupon until it matures, and when maturing, it promises to pay a principal of 1. The baseline coupon payment κ is normalized so that the price of risk-free bond equals to 1 (see [Aguiar and Amador \(2021\)](#)). With this specification, a unit of bond issued today is a contract that promises to pay debt service tomorrow of $\lambda + (1 - \lambda)\kappa$ and of the remaining portion $(1 - \lambda)$ only if the country does not default. With long-term bonds with random decay at a constant rate, the relevant variable to keep track of is the stock of the debt that the country is owed.

At the beginning of each period, the sovereign chooses to default on its debt or repay the maturing principal and coupon. If default is chosen, the sovereign is exempted from its debt obligations, but default generates two costs: 1) it generates a direct output cost, which is captured by $def(y)$, and 2) the sovereign is excluded from the global credit markets and cannot borrow for a period of time. If repayment is chosen, the sovereign pays the total debt service which is proportional to the stock of outstanding debt and raises a new revenue by issuing new bonds. Consumption takes place using the exogenous output and new bond revenue after serving the outstanding debt. The sovereign is risk-averse. The sovereign's problem is described as follows.

The sovereign, at the beginning of each period, chooses to repay or not. The value $V(y, b)$ is the value at state (y, b) , $V^R(y, b)$ is the value under repayment and $V^D(y)$ is the value under default. That is:

$$V(y, b) := \max \{V^R(y, b), V^D(y)\}$$

The function $D(y, b)$ is the default policy function where it equals to 1 when $V^R(y, b) < V^D(y)$.

Under default, the sovereign is free from its debt obligations, but suffers a direct output cost and is excluded from the credit market. It cannot borrow, but in the next period with some probability, it re-enters the credit market starting from zero debt. The parameter θ is the probability that the country re-enters the credit market under default status.

The value of default is:

$$V^D(y) = u(def(y)) + \beta \mathbb{E}_{y'|y} \{ \theta V(y', 0) + (1 - \theta) V^D(y') \}$$

Under repayment, the sovereign pays the debt service, coupon payments, and the principles of matured debt, and chooses the stock of debt tomorrow, b' . By doing so, the sovereign issues new bonds, $b' - (1 - \lambda)b$, at a price of q . As shown below, the bond price is determined by the future probability of repayment and it will depend on tomorrow's stock of debt b' . An innovation of this paper is that bond price also depends on the sovereign's credit rating. The credit rating matters because it determines in which credit market the sovereign sells its bond. When the sovereign's credit rating is high, it sells its bonds in a high-rating bond market, whereas when it has a low rating, it sells in a low-rating bond market. How the two credit markets are different is explained in the market segmentation section.

The function $u(\cdot)$ is the sovereign's utility function. β is the sovereign's discount factor. The sovereign chooses its optimal debt issuance to smooth its consumption under the budget constraint (3).

$$V^R(y, b) = \max_{c, b'} u(c) + \beta \mathbb{E}_{y'|y} \{ V(y', b') \}$$

$$s.t. \quad c + (\lambda + (1 - \lambda)\kappa)b = y + q(b', R(b', y))(b' - (1 - \lambda)b) \quad (3)$$

The debt issuance policy function $B(y, b)$ is determined from this optimization problem.

4.4 Credit rating

In each period, the sovereign's credit rating, r , is assigned. The credit rating takes two values: $r \in \{h, l\}$.¹² Investment-grade bonds are high rating bonds ($r = h$), and junk bonds are low rating bonds ($r = l$). I assume that there is no incomplete or imperfect information in the model.¹³

As in the real world where credit ratings reflect the credibility of the country's debt obligations, in the model, the credit rating reflects the sovereign's default probability. If the sovereign is likely to default in the next period, a low rating is assigned to the bonds, and vice versa. I assume that the assignment of a rating follows an exogenous rule, which is characterized by a rating rule parameter, \bar{p} . This parameter serves as a threshold between high and low ratings: if the sovereign's default probability next period is higher than \bar{p} , the country's bonds are assigned low rating and vice versa. It is important to remember that a credit rating is assigned after the sovereign's debt issuance choice. Therefore, the sovereign takes into account that its debt choice affects how its bonds are rated.

The credit rating is assigned as follows. For each state s , given sovereign's debt choice b' ,

$$R(b'(s), s) = l \quad \text{if} \quad \mathbb{E}_{s'|s}(D(s', b'(s))) > \bar{p} \quad (4)$$

$$R(b'(s), s) = h \quad \text{if} \quad \mathbb{E}_{s'|s}(D(s', b'(s))) \leq \bar{p} \quad (5)$$

The function $R(b'(s), s)$ is the rating policy function under the rule \bar{p} .

4.5 Global credit markets

There are two credit markets; one for high rating bonds and one for low rating bonds. Each market is perfectly competitive and is composed of a continuum of lenders. Lenders in each market are homogeneous, and therefore, each market has a representative lender. Both representative lenders are risk-neutral and have deep pockets. I assume that the credit markets are segmented: the representative lender of the high rating bonds markets purchases and holds the high rating bonds and they cannot purchase and hold the low rating bonds,

¹²Credit rating agencies, like Moody's and S&P, issue sovereign credit ratings with the highest AAA+ and the lowest D. There are 20 different levels of credit ratings.

¹³There are literature studies on sovereign credit ratings under the global game framework. See [Carlson and Hale \(2006\)](#), [Holden et al. \(2012\)](#), [Holden et al. \(2018\)](#)

and vice versa.¹⁴

Each lender maximizes the expected profit from holding the sovereign's risky bonds. In each period, the representative lender purchases bonds at the market price. The payoff of the bonds is conditional on the country's repayment next period and consists of debt services and the market value of the remaining bonds next period.¹⁵ In equilibrium, the bond price schedules of high and low rating bonds satisfy a zero expected profit for each lender.

The main assumption is that the two lenders are different in terms of their discount factors: $\frac{1}{R_h}$ for the high rating bond market lender and $\frac{1}{R_l}$ for the low rating bond market lender. I normalize R_h to a risk-free rate.

It is reasonable to assume that $R_l > R_h$, which means the lender in the low-rated bond market is more impatient than the high-rated bond market lender. Because hedge funds usually seek high-return investment through short-selling and speculative investment practices, their outside investment options are higher than those of commercial banks and pension funds. Therefore, sovereign bonds that are junk-rated need to compensate hedge funds to find investing in junk bonds is as profitable as investing in high-yield outside options. In addition, investing in junk bonds involves regulatory costs that financial institutions have to bear, for example, higher capital requirements and not being counted as eligible collateral by central banks. Pricing of junk bonds incorporates the compensation for those costs. It also captures the different risk tolerance between traditional financial institutions and hedge funds.

The pricing equations for each market are as follows. For each state, and given the country's choice of b' , the pricing schedule for high rating bonds is

$$q(b', s, R(b', s)) = h) \\ = \frac{1}{R_h} \mathbb{E}_{s'|s} \left[(1 - D(b', s')) (\lambda + (1 - \lambda)\kappa + (1 - \lambda)q(B(b', s'), s', R(B(b', s'), s'))) \right]$$

¹⁴I do not allow lenders to choose which rated bonds to hold but take it as exogenous. This enables the model to be solved in a tractable way, especially the pricing schedules.

¹⁵When the country is either upgraded or downgraded next period, the current bondholder can no longer hold the bonds and has to sell the holding bonds to the secondary market. When the country keeps its rating, the current bondholder can sell the bonds or resell them to the secondary market. I assume both primary and secondary markets are perfectly competitive, and the secondary market has no liquidity friction. Therefore, primary and secondary markets share the same market price schedule, and I can recursively express bond prices with a single price schedule.

The pricing schedule for low rating bonds is

$$\begin{aligned}
 q(b', s, R(b', s) = l) \\
 &= \frac{1}{R_l} \mathbb{E}_{s'|s} \left[(1 - D(b', s')) (\lambda + (1 - \lambda)\kappa + (1 - \lambda)q(B(b', s'), s', R(B(b', s'), s'))) \right]
 \end{aligned}$$

It is important to notice that both pricing schedules are the same except for the discount factor. Regarding the pricing of the bonds, not only does its expected payoff next period matter, but also the bonds' rating, thus to whom the bonds are sold. Furthermore, the bond price incorporates the expected value of the remaining bonds next period, which depends on the credit rating next period. Assuming that the discount factor of the representative lender of low rating bonds market is low, the more likely it is that the sovereign's bonds will be low rating tomorrow, the lower the value of the remaining bonds next period. This expectation is embedded in the pricing schedules. The bonds could be priced relatively low even though it is high rating, if there is a high chance of downgrade next period.

Another important feature of the model is the endogenous response of the sovereign. This response is embedded in the pricing equations above. The equilibrium pricing schedules depend on the sovereign's policy functions. The sovereign internalizes how its borrowing decision affects its credit rating and therefore the pricing schedule that it faces. The impatient sovereign has a temptation to front-load consumption, which is a main driver of high borrowing. Long bond maturity is another factor of high borrowing. The opposite tensions of high borrowing are present in the model. It is not only the fact that the bond is devalued by the default risk but also the fact that borrowing over a certain threshold (so that the sovereign downgrades to low rating) triggers another bond devaluation by the low discount factor of the representative lender of low rating bonds market. The sovereign internalizes this devaluation.

4.6 Markov equilibrium

I define a Markov equilibrium of the economy as follows. Given the exogenous rating rule \bar{p} , a Markov equilibrium consists of the sovereign's value functions $V(b, s)$, $V^D(y)$, $V^R(b, s)$, the sovereign's policy functions $B(b, s)$, $D(b, s)$, rating policy function $R(b', s)$ and bond pricing schedule $q(b', s)$ such that

1. Given the rating policy function and the bond pricing schedule, the sovereign's value functions and policy functions satisfy the sovereign's bellman equations and maximization problems.

2. Given the sovereign’s policy functions, the rating policy function is consistent with the rating rule \bar{p} .
3. Given rating policy functions and the sovereign’s policy functions, the bond pricing schedule satisfies zero expected discounted profit conditions.

4.7 Bond maturity and efficiency

The literature on quantitative sovereign defaults suggests that the maturity of bonds plays a crucial role in the sovereign’s borrowing behavior (see [Hatchondo and Martinez \(2009\)](#); [Chatterjee and Eyigungor \(2012\)](#); [Hatchondo et al. \(2016\)](#)). The literature finds that debt dilution happens under long-term debt, and it creates overborrowing inefficiency. Debt dilution means the reduction in the value of outstanding debt caused by new debt issuance. This happens because sovereigns cannot commit, at the time of borrowing, the borrowing behavior of future sovereigns. Long-term bond allows the sovereign to postpone the costs of current borrowing to the future sovereign. Given today’s borrowing, the future sovereign has incentives to borrow high and the current sovereign is limited to constrain it. Rational lenders anticipate that additional borrowing by the future sovereign will increase default risk and reduce the market value of bonds issued by current sovereign. The bonds issued in current period is low-priced, and the sovereign has to issue more debts in order to raise a certain level revenue.

[Chatterjee and Eyigungor \(2012\)](#) quantifies debt dilution inefficiency by comparing equilibrium with long-term and with one-period debt. They find that sovereign’s welfare is highest for one-period debt and declines monotonically as maturity parameter increases. [Hatchondo et al. \(2016\)](#) compare long-term bond equilibrium with dilution effect and without dilution effect, and find that the one with dilution has higher debt level and more frequent defaults. These findings suggest that long-duration maturity induces the sovereign to borrow more due to debt dilution problem, and it is welfare-reducing.

[Aguiar and Amador \(2019\)](#) find that borrowing is constraint efficient in one-period-bond [Eaton and Gersovitz \(1981\)](#) model by using dual-contracting approach. Constraint efficiency here means Pareto-optimal allocation between lenders and sovereign in the presence of market incompleteness and lack of commitment on default decision next period. Bond maturity plays a vital role in determining the welfare implications of market segmentation in this paper. I will explain the details in Section 7.6.

Table 4: Parameters calibrated outside of the model

| Parameter | Description | Value | Source |
|-----------|-------------------------|--------|------------------------------|
| σ | Risk aversion | 2 | Literature |
| ρ | Output persistence | 0.844 | The panel data |
| η | Output volatility | 0.034 | The panel data |
| R_h | High rating market | 1.0217 | Risk-free rate |
| λ | Bond structure | 0.2 | 5-years maturity |
| ξ | Re-entering probability | 0.1538 | Chatterjee, Eyigungor (2012) |
| \bar{p} | Rating rule | 0.0064 | Moody's rating rule |

5 Calibration

The model is calibrated to a yearly *monthly* frequency. The parameters of the economy are chosen either from outside of the model or by matching moments. The model targets the average across countries in the panel data. The details of the calibration strategy are in the Appendix.

The flow utility function is specified as constant relative risk aversion (CRRA) utility on consumption:

$$u(c) = \frac{c^{1-\sigma} - 1}{1 - \sigma}$$

The default cost is in units of output. Following [Arellano \(2008\)](#) and [Chatterjee and Eyigungor \(2012\)](#), it is non-linear in output, where parameters d_0, d_1 control the incentive to default. These parameters are calibrated by matching moments, as described below.

$$def(y) = \max\{0, d_0 + d_1 y\}$$

[Table 4](#) shows the list of parameters that I have calibrated outside of the model. The country's risk aversion σ is set to the standard value in the literature. The stochastic output is assumed to follow an AR(1) process and is estimated from the emerging market panel data. For each country, I linearly detrend real GDP growth and estimate an AR(1) process from the cyclical components. I take the sample mean on estimated output process weighted by data observations.¹⁶ The estimated value for persistence and volatility on output are $\rho = 0.84$ and $\eta = 0.03$ for each. Consistent with the previous literature, as in [Neumeyer and Perri \(2005\)](#) and [Aguiar and Gopinath \(2007\)](#), the estimated parameter features the

¹⁶The dataset is not balanced, and some countries, for example Azerbaijan and Namibia, have fewer observations on spreads.

emerging market’s volatile output.

I normalize the discount rate of the high-rated bond market to be the international risk-free rate. I take U.S. Treasury security as the benchmark safe asset. The risk-free rate is set as the one-year U.S. Treasury market yield average from FRED in the year 1998 to 2019 (the same period as the panel data). The bond maturity parameter λ is set to resemble the 5-year maturity bond. The parameter ξ represents the re-entering probability after default and financial exclusion. Based on Chatterjee and Eyigungor (2012), the value of ξ is set to match the average autarky period, which is approximately 6.5 years.

The rating rule parameter \bar{p} is taken from *idealized cumulative expected default rates*¹⁷ released by Moody’s (2018), one of the major credit rating agencies. These rates suggest the benchmark expected default rates where a rated-counterparty will fail to perform its debt obligation (Moody’s (2022)). The rates are available for each rating level. Since the model is in a yearly frequency, the rates in the 1-year horizon are used for the estimation. Since \bar{p} captures the threshold of credit ratings under regulatory purposes, I take the mean of expected default rates of the Baa3 rating and the Ba1 rating. The estimated value of \bar{p} is 0.64%. It means that in the model country is low-rated if it is expected to default at a higher rate than 0.64% next period.

5.1 Calibrated parameters

The rest of the parameter values are jointly calibrated by matching moments. A key parameter is the discount rate of the low rating market R_l which governs the degree of market segmentation. I calibrate the segmentation parameter to target the downgrade coefficient in the analysis of Section 4. To be specific, I run the same regression using the model simulation as in Section 4. In the model simulations, the downgrade dummy variable captures downgrades from $r = h$ to $r = l$. I use the same controls for this regression as in the data: output level y , debt-to-output ratio b/y , and the last period spread. I do not control for country-fixed effect and time-fixed effect in the model simulation because it is a single-country model and because there is no exogenous time-varying risk-free rates.¹⁸

Following the literature, the country’s discount factor β and default cost parameters d_0, d_1 are mapped to the mean debt-to-output ratio, mean spread level, and the standard deviation

¹⁷The word idealized may imply a potential discrepancy between the expected default rate by the time the credit rating agency assigns a rating to the entity and the default rate afterwards. The default risk estimate using historical ratings path could be different from the initial design of each rating category.

¹⁸Including time-fixed effect in the data is to control time-varying risk-free rates and risk premium. Another purpose is to improve on the frequency issue of macro-fundamental variables. The spread movement within a year could potentially result from the fundamental change within a year. This is hard to capture using yearly data. Month-year fixed effect can control this potential fundamental change. In the model, the current spread perfectly captures the fundamental change between last period and current period.

Table 5: Parameters calibrated inside of the model

| Parameter | Description | Value | Moments | Target | Model |
|-----------|----------------------|--------|-----------------------|---------|---------|
| R_l | low rating market | 1.047 | downgrade coefficient | 29.64 | 29.98 |
| β | country's impatience | 0.918 | mean b/y | 47.1 % | 25.5 % |
| d_0 | default cost | -0.217 | mean spread | 294 bps | 293 bps |
| d_1 | default cost | 0.254 | s.d. spread | 1.67 | 1.37 |

of the spread. The data moments are calculated as sample averages across countries in the panel data. In the end, I calibrate the segmentation parameter R_l , country's impatience β , and default cost d_0, d_1 jointly to match the four moments: the downgrade coefficient, the mean debt-to-output ratio, mean spread level, and the standard deviation of the spread.

Table 5 show the calibrated values for four parameters and the targeted moments. The model has a limitation in matching the mean debt-to-output ratio. It is because high enough R_l relative to β is necessary for generating the downgrade coefficient, but that R_l discourages the sovereign from accumulating the debt in the model simulation. On the other hand, low enough β relative to R_l weakens the segmentation effect, and the downgrade coefficient is not generated under the model simulation. Including the variance of taste shock in the calibration can potentially improve on debt-to-output ratio matching. ¹⁹

6 Quantitative results

I now describe some features of the Markov equilibrium in the calibrated model. To understand the role of sovereign ratings, I compare the benchmark model to a counterfactual economy with no ratings and no market segmentation. I demonstrate the disciplinary role of ratings.

6.1 The equilibrium bond pricing schedule

Figure 3 depicts the equilibrium bond spread schedule as a function of the debt choice b' . The schedule is evaluated at the mean y level, and the b' level in the horizontal axis is relative to the mean y level. The junk cutoff indicates that the country's rating is high with a lower b' level than the cutoff, and a higher b' level than the cutoff produces the low rating for the country. As usual, the spread schedule is upward-sloping: the higher b' level increases the

¹⁹Following Dvorkin et al. (2021), I employ extreme value shock to tackle computational issues solving a sovereign default model with long-term bond. Taste shock-related parameters are directly taken from the literature for now, but potentially I can include those parameters in the joint calibration. For the literature to include taste shocks in the calibration, see Arce (2021).

Figure 3: The equilibrium bond pricing schedule

Note: This figure plots the equilibrium bond spread calculated from the equilibrium bond price schedule, q , in two economies. The spread is annualized and over risk-free rate, R_h . Conditional on the mean output level, the calculated spread is plotted as a function of the debt level, b' . The x-axis represents the debt level, and the y-axis is expressed as basis points (bps). The blue line represents the benchmark economy, while the black dash line represents the counterfactual economy without the segmentation. The "junk cutoff" indicates the maximum level of debt where the country's credit rating is considered high.

equilibrium spread. A high level of debt choice today means a high level of outstanding debt tomorrow, raising the sovereign's incentive to default tomorrow. That higher default risk requires a higher interest rate (or a lower bond price). The upward-sloping pricing schedule is present in both the benchmark and the counterfactual.

Unlike the counterfactual, the first distinctive feature of the benchmark is a discontinuity. This discontinuity arises from the segmentation by credit ratings. As the debt choice b' increases above the cutoff, the country's default probability increases above the rating rule threshold, \bar{p} , and the country's rating changes from high to low. As the country's rating changes from high to low, the lender who prices the bond switches from the patient lenders (the lenders in the high-rated bond market) to the impatient lenders (the lenders in the low-rated bond market). This switch means a discrete change in the discount rate of the equilibrium pricing equation. This discrete increase in interest rate is the driving force of the disciplinary effect on sovereign's borrowing. As shown in the counterfactual, the default risk

compensation grows smoothly as the default risk increases around the threshold. Therefore, the discrete increase in the spread is not from default risk compensation but from the switch to a different credit market.

Another feature of the pricing schedule is the presence on anticipation effect. Note that the bond in the model is a long-duration bond. Thus, the bond price reflects all the future credit ratings and default probabilities. If the country downgrades to a low rating tomorrow, the market value of its bonds tomorrow will be low. Even though the sovereign's rating is high today and patient lenders price the bond with a low yield, the bond price could be noticeably low if there is a high probability of a downgrade tomorrow. That is, the expectation of future downgrades forces the devaluation of bonds in the current period. This devaluation is visualized when b is lower than the threshold but substantially high enough: the spread increases faster as b' rises closer to the threshold. This more rapid growth in the spread (or faster devaluation of the bonds) is not because the default risk evolves faster under the benchmark ²⁰ but because downgrades in the next period are more likely to be anticipated.

Combining the first and the second features tells us how the discontinuity is determined in the model. The discontinuity is higher as the R_l parameter increases. On the other hand, the greater the anticipation effect is, the lower the discontinuity is. The country's borrowing incentives govern the anticipation effect. In particular, they govern how likely it is that a downgrade will happen next period and how likely it is for the downgrade to revert if that happened. The country's impatience and default cost parameters are relevant for the borrowing incentives. The downgrade coefficient captures this discontinuity under the simulation. To identify R_l in the model, I need to consider the interaction of this discontinuity with other parameters, which provides a rationale for the joint calibration.

The last feature to highlight is the lower spread in the benchmark under a low enough level of b' . As long as b' is low and downgrades are less likely to happen tomorrow, the sovereign can borrow cheaply. This cheap borrowing arises from the disciplined borrowing and lower probability of default, a result that is explained in detail in the following subsections.

6.2 The optimal policy of the sovereign

Figure 4 shows the optimal policy of the sovereign in the benchmark calibration. The borrowing policy is shown as a function of the outstanding debt level b evaluated at the mean y level. The level of the horizontal axis is normalized by the mean y level. The function is weakly increasing in b , which means the sovereign finds it optimal to choose a

²⁰The growth rate of default probability with b' around the cutoff under the benchmark is almost equivalent to the one under the counterfactual.

Figure 4: Sovereign's borrowing policy

Note: This figure plots the equilibrium debt issuance policy function, $b'(b)$, in two economies. Conditional on the mean output level, the optimal debt choice is plotted as a function of the debt level, b . Both x-axes and y-axes represent the debt level relative to the mean output level. The blue line represents the benchmark economy, while the black dash line represents the counterfactual economy without the segmentation. The "junk cutoff" indicates the maximum level of debt where the country's credit rating is considered high.

high b' when it inherits a high level of b . It is because the sovereign rolls over the inherited debt and, conditional on repayment, consumption which the sovereign gains flow utility from reduces with a higher outstanding debt. The junk cutoff denotes the level of debt such that at the given y if the government chooses b' above it, its rating is low. Therefore, the government faces today the impatient lenders of the low-rated bond market.

The distinguishing feature under the benchmark is that the sovereign stops borrowing near the cutoff. To be more precise, the country reduces the debt stock to a level right below the cutoff. That is, the sovereign internalizes the consequence of borrowing over the cutoff. In the simulation, the sovereign finds it optimal to keep its high rating and avoids the high yield from the impatient lenders. However, reducing borrowing means less consumption and less flow utility today. With a high enough outstanding debt level, the country has no choice but to cross the threshold and as a result, its bonds are low rated. But still, the sovereign chooses less debt than it would have chosen in the counterfactual; the country exits the low-rating territory by gradually reducing debt until above, but nearby the threshold.

Not only when the state is near the cutoff, but less borrowing is also present in the

entire debt state b , including when the country’s rating is high and is far from the cutoff.²¹ This less borrowing can be interpreted as a precautionary behavior of risk-averse agents in the incomplete market (Aiyagari (1994)). A sufficient negative output shock could lead to downgrades, and the country pays the high yield as a consequence. Due to an incomplete market structure, the government cannot hedge from this output shock and the following rating downgrades. Instead, the risk-averse government chooses to borrow less out of the precautionary motive, even when the state is far away from the cutoff. By doing so, the probability of downgrade, which comes from the sufficient negative output shock, is low. This motive becomes more apparent as the probability of downgrades rises: as the state is closer to the cutoff, the government chooses to borrow much less. Less borrowing in the entire debt region lowers the default probability, and the pricing schedule embraces it. Therefore, the sovereign can borrow at a lower spread under a high rating than it would have had in the counterfactual, as shown in Figure 3.

6.3 Simulation

Table 6 compares the model simulation result to that of the counterfactual economy. To make this comparison, I feed the same time series of stochastic variables, the output series and the re-entry shock upon default. After discarding the first 100 periods of each simulation, I imposed the same initial debt level of the benchmark simulation on the counterfactual simulation. Each simulation is over 1,000 periods, and the listed moments are calculated as the sample average over 100 simulations. Percentage change denotes the percentage change of the moment under the benchmark relative to the counterfactual. The periods when the country is in default are not included in calculating the moments.

As documented before, a lower mean debt level relative to output in the benchmark is expected. Regarding the average spread, disciplined borrowing lowers the incentive to default at a given output level and could result in a lower spread, especially when the country’s rating is high. On the other hand, the presence of impatient lenders could contribute to a higher spread on average when low ratings happen frequently. Under the calibration simulation, the country’s rating is high as often as 63%, and the average spread of the benchmark economy is lower than without ratings.

Another finding is that the country’s default risk is lower with the segmentation by ratings, and fewer defaults happen on the equilibrium path. This result is consistent with a lower spread volatility and mean spread. Spread surges are observed with high default

²¹The entire debt state refers to a set of debt state $[0, \bar{b}]$ where the default probability reaches to 1 under \bar{b} given y as the mean level. In this region, the optimal borrowing in the benchmark is strictly lower than that in the counterfactual.

Table 6: Model simulation results

| | benchmark | counterfactual | % change |
|----------------------|-----------|----------------|----------|
| mean default risk | 1.83 % | 2.60 % | - 30 % |
| junk freq. | 37 % | 51 % | - 27 % |
| annual default freq. | 1.7 % | 2.5 % | - 32 % |
| mean debt/y | 25.5 % | 26.9 % | - 5 % |
| mean spread | 293 bps | 313 bps | - 6 % |
| s.d. spread | 1.37 | 1.45 | - 6 % |

Note: This table reports simulated moments in two economies. Each simulation is over 1,000 periods, and the listed moments are calculated as the sample average over 100 simulations. The first 100 periods for each simulation is deleted as well as periods in financial autarky and 50 periods upon re-entering to financial market.

risk, which contributes to high spread volatility. Frequent downgrades could also contribute to higher spread volatility, as the spread surges discretely with the switching to impatient lenders. Despite the small magnitude of the reduction in spread volatility compared to the significant reduction in default risk, the first force quantitatively dominates the second force, resulting in lower spread volatility under the benchmark.

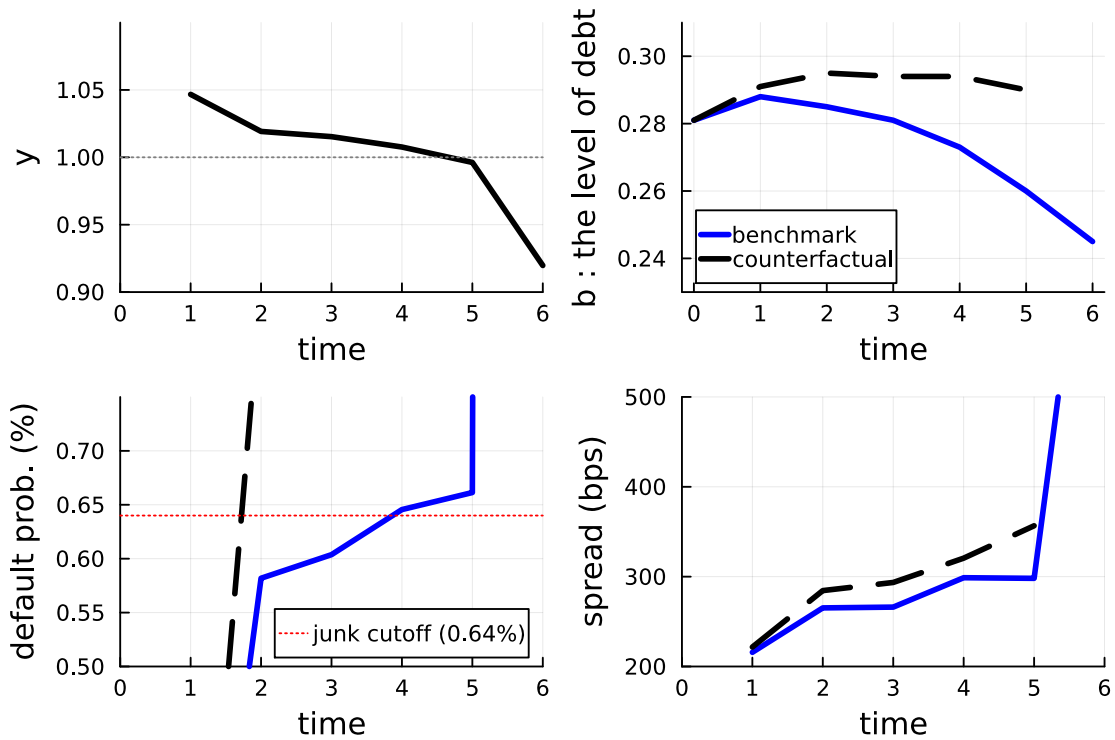

The fact that the reduction in default risk is relatively significant compared to the decrease in mean debt level highlights the crucial role played by the segmentation by ratings. This segmentation restricts the country from remaining in a positive default risk state, thereby preventing the default risk from evolving further. This is supported by the optimal borrowing policy, which reveals that the debt reduction is most pronounced near the cutoff or low-rating territory, where the default risk is strictly positive, and the economy is vulnerable to adverse output shocks.

6.4 Debt dynamics in recession

Figure 5 illustrates that the segmentation keeps the debt stock low, which prevents default from happening. To assess the impact of the segmentation, I simulate an output process that reflects a recession in both the benchmark and counterfactual economies. The process begins with a high level of output, gradually declines, and experience a significant drop at time $t = 6$. The two economies start with the same initial debt level. Given this output process and initial debt level, I plot the equilibrium debt level, default probability, and spreads over time. The unit of time is a year.

In the counterfactual economy, the sovereign defaults at $t = 6$, whereas in the benchmark economy, it manages to survive the recession without defaulting. The likelihood of default

Figure 5: Debt, default probability, and the spreads dynamics during recession

Note: This figure illustrates the evolution of the debt level, default probability, and equilibrium bond spread in two economies, given a specific output process (top left). Both economies start with the same debt level, equivalent to 28% of the mean output level. The "junk cutoff" denotes the threshold level beyond which the country is rated as having a low credit rating. All x-axes represent time.

increases as the sovereign holds a higher level of debt and as the output level drops. During a recession, defaults could happen in equilibrium when the sovereign is sufficiently indebted. At $t = 6$, when the output level drops significantly, the counterfactual economy had a debt-to-GDP ratio of up to 29%, making repayment costly for the government. In contrast, the benchmark economy had a debt-to-GDP ratio of only 26%, which is attainable because the government starts reducing the debt stock from $t = 2$. As the output level falls from $t = 2$, the default probability increases, bringing the economy closer to the junk cutoff. By $t = 4$, the country is rated as junk in the benchmark. The segmentation encourages the government to reduce its debt stock, keeping the default risk relatively low and the economy less vulnerable to sudden output drops. At $t = 5$, the default probability under the benchmark is approximately 0.66%, while under the counterfactual, it is as high as 3%.

The right bottom panel of [Figure 5](#) displays the bond spreads of the two economies. In general, the spreads in the counterfactual economy are higher than those in the benchmark economy. Even though the discount rate in the counterfactual economy is equal to or lower than that in the benchmark economy, the sufficiently high default probability in the counterfactual offsets the high discount rate of the junk-rated bond market in the benchmark. One interesting observation is that due to the anticipation effect, the movement of spreads upon downgrade is relatively smooth. From $t = 3$ to $t = 4$, the government is downgraded to junk. Although the bond at $t = 4$ is discounted more by 200 bps, the spreads increase by approximately 30 bps. This is because the spreads at $t = 3$ already include the possibility of a downgrade next period and incorporate the difference in the discount rate before the downgrade.

6.5 The welfare implications of ratings

In this section, I discuss how the ratings and resulting segmentation affects the sovereign's welfare. [Figure 6](#) shows the percentage change in welfare under the benchmark compared to the counterfactual, the economy without segmentation. The welfare is in consumption equivalent units. I can define welfare in a following way:

$$1 + \Lambda(b, s) = \frac{V_{NS}(b, s)^{\frac{1}{1-\sigma}}}{V_S(b, s)} \quad (6)$$

where $V_{NS}(b, s)$ is the value of the sovereign at state (b, s) in benchmark economy with segmentation, and $V_S(b, s)$ is the value of sovereign at state (b, s) in counterfactual economy without segmentation. A positive number means the segmentation generates welfare gain for the sovereign. I plot the welfare for different initial debt levels b_0 and for a given mean y level.

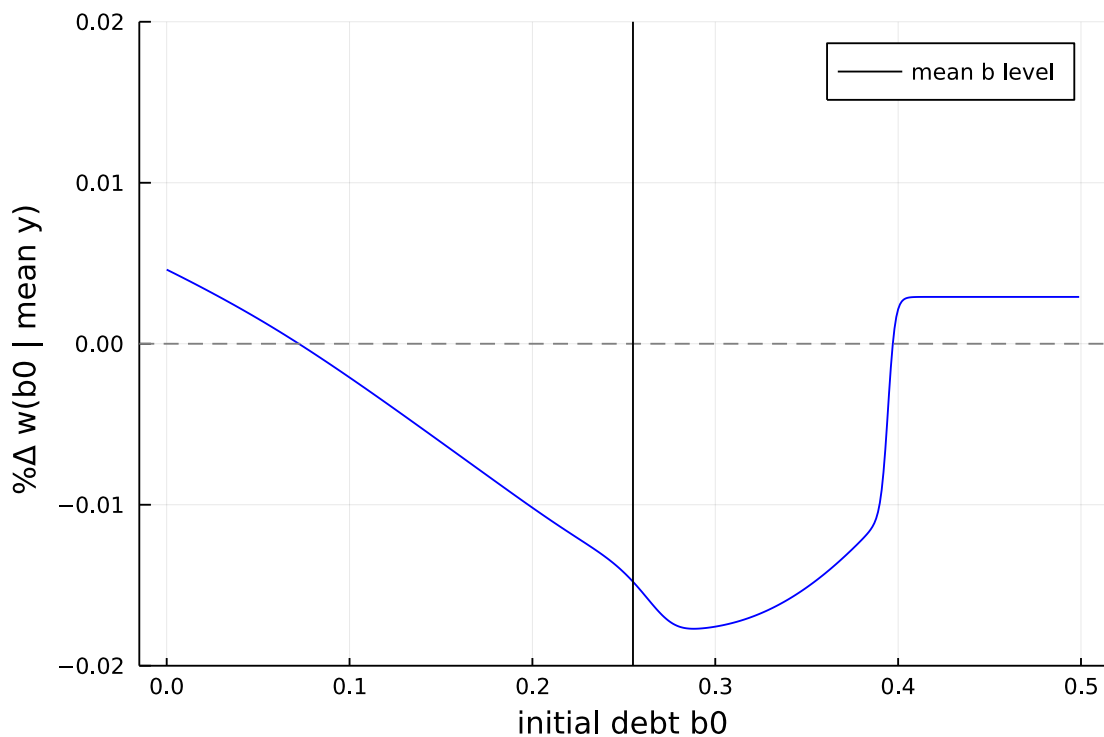

Figure 6: The welfare under the segmentation

Note: This figure plots the country's welfare under segmentation as a function of initial debt level. The welfare is calculated as in (6), capturing the difference in the country's value in the benchmark and counterfactual economies. The positive welfare means the country has a higher level of welfare in benchmark than in counterfactual. The y-axis is in terms of percentage points.

The difference in welfare is a decreasing function of debt for low levels of the initial debt. It is because the welfare benefit from the segmentation decreases with the high debt level, whereas the welfare cost rises with the high debt level. Those opposite forces help to understand the welfare implications of segmentation. The disciplining behavior of ratings lowers the country's default risk and allows the government to borrow at a better price, which is a potential source of welfare benefit. This benefit is maximized when the debt state is far from the junk cutoff at a given y level. As the debt state is closer to the cutoff, the anticipated bond devaluation counteracts the disciplinary effect, and the welfare benefit is reduced. Although the sovereign currently maintains a high rating, there is a decent chance that the country may be downgraded to junk next period when the debt state is close enough to the cutoff.

The primary source of welfare cost is low consumption from reducing debt issuance. In this model, the country's welfare is derived from the flow utility from consumption. As the debt state is closer to the cutoff at a given y level, the government actively shrinks the bond issuance, and the welfare cost from low consumption amplifies. Not only is reducing debt stock painful to the country, but the high yield from the impatient lenders is also a crucial source of welfare cost. Adverse output shocks trigger downgrades to low ratings, and the sovereign pays high yields to impatient lenders in addition to a high default risk compensation. This is not ideal from the perspective of risk sharing: the sovereign may want to hedge from low-income shock.

Figure 6 shows how each opposite force aggregates quantitatively. First, the segmentation delivers a welfare loss to the sovereign in the stationary debt level. The percentage change in welfare under the mean debt level is negative under the calibration. The calibrated sovereign is so impatient that it accumulates debt sufficiently close to the cutoff. The anticipated devaluation counterbalances the welfare benefit from the segmentation, at the same time the country suffers from controlled borrowing as it is near the cutoff. Moreover, the government is exposed to a decent chance of downgrades next period (coming from low-income shocks). In the end, the welfare cost quantitatively dominates the welfare benefit, and the welfare loss, in the long run, is as much as around -0.015% under the calibration.

However, the country gains welfare from the segmentation at low debt level. As long as the country is far from the cutoff, downgrades rarely occur in the near term, and the government does not need to reduce the debt issuance aggressively. The benefit of borrowing at a better price is maximized without anticipated depreciation. Quantitatively, the country's welfare is enhanced by the segmentation by roughly 0.005%. Also, the welfare gain happens under the default region. The debt region over the level of 0.4 visually shows it. In this model, the country in default status returns to the credit market with zero debt, where the welfare

benefit is maximized.

6.6 The role of bond maturity

Figure 7: The welfare under the segmentation with different bond maturity

Note: This figure illustrates the country's welfare under the segmentation as a function of initial debt level in two economies: the red line represents an economy with one-period debt, and the blue line represents the benchmark economy. The welfare is calculated similarly as in Figure 6.

Here, I study how the welfare results change with different bond maturity. Figure 7 outlines the sovereign's welfare as in Figure 6, but I vary bond maturity parameter, λ . The blue line is the benchmark where it captures 10-years maturity whereas the red line is with $\lambda = 1.0$, which is 1-year maturity. Under one-period bond, the debt service for debt stock b is $(\lambda + (1 - \lambda)\kappa)b = b$. It means that the total principle of outstanding debt should be paid in order to raise new bond revenue. This is different from the benchmark where the sovereign can raise new revenue as long as at least 10% of outstanding debt is repaid. I keep all other parameters, other than κ , the same in the counterfactual.²²

²²In the benchmark, coupon parameter κ is normalized so that the bond price with zero risk is equal to 1. Under one-period bond case, every bond matures next period, and there is no notion for coupon. Under one-period bond case, I set $\kappa = 0$

With $\lambda = 1.0$, the sovereign’s welfare under the segmentation is negative across all debt levels, suggesting that the sovereign is always worse off with the segmentation under this calibration. The main friction under one-period debt is that sovereigns cannot commit, at the time the debt is issued, on their next period default decision. Adding the segmentation cannot resolve commitment issue on not defaulting next period under [Eaton and Gersovitz \(1981\)](#) timing. Given the current debt level, the probability of default in the next period is contingent on the exogenously drawn output level, which follows a stochastic process. As the debt level increases, the sovereign’s credit rating approaches the junk cutoff, and the associated welfare cost rises. At sufficiently high levels of debt, the sovereign chooses to default. In this case, the sovereign’s value is independent of the debt level, and this is represented as a horizontal line for debt-to-GDP ratios higher than around 32%.

The finding that the sovereign can benefit from segmentation under long-term debts suggests that segmentation can partially address the issue of lack of commitment regarding future borrowing. The segmentation works as a commitment device by influencing market prices for future borrowing. When new debt is issued, lenders anticipate that the future sovereign is limited to borrow more, especially borrow beyond the junk cutoff. The future value of outstanding debt will not be diluted as much, and the lenders are willing to pay a higher price for current debt. This partially resolves the welfare-reducing debt-dilution problem, and the sovereign can benefit under sufficiently low levels of debt. This result is consistent with the existing literature. As an alternative solution to the debt-dilution problem, [Chatterjee and Eyigungor \(2012\)](#) suggests fixing the future value of outstanding debt at its value at issue. The segmentation can be viewed as a lower bound of the future value of outstanding debt.

6.7 Different segmentation rules and welfare implications

In this exercise, I vary the rating rule parameter, \bar{p} , and analyze how it affects the sovereign’s welfare. The benchmark rule segments the credit market between BBB-/Baa3 and BB+/Ba1, which distinguishes between investment-grade and junk. [Figure 8](#) shows the percentage change in welfare with different segmentation rules normalized by welfare under the benchmark. I map the \bar{p} values to the rating level according to Moody’s rating rule, which I use in calibration. The assumption is that each segmented market has the same discount rate as in the benchmark. The welfare change is evaluated under the mean output level y with two different initial debt levels: starting the economy with zero or the mean debt level in the benchmark.

The result suggests that the current rule is reasonable, whereas the optimal segmentation

Figure 8: Change in welfare under the counterfactual segmentation

Note: This figure illustrates the welfare under the segmentation with different rating rules. The x-axis represents a counterfactual junk cutoff below which the country is rated as high. The welfare is calculated for each counterfactual rating rule and in a similar fashion as in Figure 6.

rule is a bit looser than that. Under the calibration, between BB-/Ba3 and B+/B1 is the optimal rule, and the country is better off even at the mean debt level. The sovereign is significantly impatient in the calibration, and looser rule can reduce the welfare cost. However, if the rule is loosened too much, it reduces welfare because it weakens disciplinary motives. On the other hand, tight segmentation rules aggravate the country's welfare.

7 Conclusion

From the regulatory usage of sovereign credit ratings, this paper highlights the disciplinary role of ratings on governments' overborrowing. I build a model of a country's borrowing, default, credit rating, and the consequent credit market segmentation. I incorporate the endogenous response of the government. This delivers a different implication of sovereign ratings in the international credit market, which the previous literature has neglected. I calibrate the segmentation parameter using the spread response to countries' downgrade to junk observed in the data. The consequence of downgrades to junk gives sovereigns

incentives to manage their credit ratings and discourages them from borrowing over the threshold. Under the calibration, downgrades to junk imply that the impatient lenders of junk bond markets charge a high yield to the sovereign. This consequence of downgrades and the country's ability to manage its ratings are the driving forces of disciplined borrowing behavior.

This disciplined behavior lowers the country's default risk and allows it to borrow at a better price, which is a potential source of welfare benefit. The welfare cost of ratings and implied segmentation is from the anticipated devaluation of bonds before downgrades and controlled borrowing when the country is near the threshold. Under the calibration, the cost dominates the benefit, and the segmentation by sovereign ratings results in welfare loss to the impatient country in the long run. However, the government gains from the segmentation during the transition, especially when the debt stock is low.

This welfare analysis suggests the importance of moderate segmentation in the international capital market. The finding suggests a rationale for the current segmentation rule. The paper proposes that loose segmentation policies weaken disciplinary motives and deliver negative welfare implications to developing countries. Imposing an adequate punishment as a form of market segmentation could alleviate commitment issues and give developing countries better credit access.

Appendices

A Appendix for Section 3

Real GDP growth The percentage change in constant price GDP. The base year is country-specific. GDP is measured as expenditure-based, meaning total final expenditures at purchasers' price less the value of imports of goods and services. Named as Gross domestic product, constant prices, percent change in the World Economic Outlook Database in the International Monetary Fund.

Real GDP per capita Purchasing power parity dollars GDP divided by total population. Named as Gross domestic product per capita, constant prices, purchasing power parity, 2017 international dollars in the World Economic Outlook Database in the International Monetary Fund.

Inflation Year-on-year change in consumer price index (CPI). CPI is calculated as the average for the year, not end-of-period data. Named as Inflation, average consumer prices, percentage change in the World Economic Outlook Database in the International Monetary Fund.

Government revenue Measured as revenue divided by national GDP. Revenue consists of taxes, social contributions, grants receivable, and other revenue. Named as General government revenue, percent of GDP in the World Economic Outlook Database in the International Monetary Fund.

Debt to GDP ratio Measured as gross debt divided by national GDP. Gross debt consists of all liabilities that require payment or payments of interest and/or principal. This includes debt liabilities, debt securities, and loans, for example. Named as General government gross debt, percent of GDP in the World Economic Outlook Database in the International Monetary Fund.

Current account Measured as current account balance divided by national GDP. Named as Current account balance, percent of GDP In the World Economic Outlook Database in the International Monetary Fund.

Sovereign credit rating the Standard and Poor's sovereign credit ratings.²³ Following El-Shagi and von Schweinitz (2018), took the last day rating for a given month in <https://countryeconomy.com/>, <https://tradingeconomics.com/>, and <http://www.worldgovernmentbonds.com/>, depending on data availability.

Note: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. Standard errors in parentheses. In all specifications, the dependent variable is EMBI+ sovereign bond spread. DowntoJunk is a dummy variable that equals 1 when a country's S&P sovereign rating is above or equal to BBB- in period $t - 1$, and below or equal to BB+ in period t . Lag spread is a 1-month lag variable.

Note: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. Standard errors in parentheses. In all specifications, the dependent variable is EMBI+ sovereign bond spread. The variable Down to Junk is a dummy variable that equals 1 when a country's S&P sovereign rating is above or equal to BBB- in period $t - 1$, and below or equal to BB+ in period t . The variable Down to BBB is a dummy variable that equals 1 when a country's rating is BBB+ at period $t - 1$ and BBB at period t . Other dummy variables, Down to BBB-, Down to BB, and Down to BB-, are constructed similarly (BBB in period $t - 1$ and BBB- in period t , BB+ in period $t - 1$ and BB in period t , and BB in period $t - 1$ and BB- in period t , respectively).

B Numerical Algorithm

The algorithm iterates on value functions, $V(b, s)$, $V^D(b, s)$ and price function, $q(b, s)$, until convergence. Using Tauchen's method, I discretize stochastic output process, y , as a Markov chain. I also discretize endogenous state variable, b into finite grid. I use 151-grid points for y , and 301-grid points for b .

The challenge of computing long-term debts has been documented in the literature. Following [Dvorkin et al. \(2021\)](#), I use Extreme Value shock to resolve this issue. I assume there is taste shock, additive utility shocks, associated with each possible debt level choice and default choice. For parameters governing the distribution of extreme value shock, I take the value from [Dvorkin et al. \(2021\)](#).

First, I set initial guesses for $V(b, s)$, $V^D(b, s)$, and $q(b, s)$. I update $V^D(b, s)$ using initial guess $V(b, s)$ and $V^D(b, s)$. Then, for each (b, s) , I use discrete-search method to calculate the optimal debt. That is, given initial guess $V(b, s)$ and $q(b, s)$, I look for a b that gives the highest value under repayment than any other b in the grid can give. By doing so, I can define debt policy function, $B(b, s)$. Given initial $V(b, s)$, $q(b, s)$ and defined $B(b, s)$, I can define value under repayment, $V^R(b, s)$. With updated $V^D(b, s)$ and $V^R(b, s)$, I can update $V(b, s)$ and define default policy function, $D(b, s)$. Given $D(b, s)$, I can calculate next period default probability for each state (b, y) . Given a rating parameter, I can define rating function, $R(b, s)$ following the rating rule as specified. Given $R(b, s)$, $D(b, s)$, and the initial $q(b, s)$, I can update price function. Rating function determines the discount rate, and initial price function is used for calculating the future value of bonds.

I check if the updated $V(b, s)$, $V^D(b, s)$, $q(b, s)$ are close enough to the initial $V(b, s)$, $V^D(b, s)$, $q(b, s)$. If it close enough within a tolerance level, I stop the iteration. Otherwise, I use the updated $V(b, s)$, $V^D(b, s)$, $q(b, s)$ as initial guesses and re-do the iteration.
